SECTION I

STATEMENT OF PROBLEM

The physical and chemical factors responsible for the maintenance of tenacious lubricating films between metal surfaces are not well understood.

From time to time, numerous chemical components have been added to commercial lubricating oils for the purpose of increasing their lubricating ability, (reducing frictional losses), improving their film strength characteristics, reducing the metal attack by components present in or formed during lubrication with hydrocarbon lubricants, and for other stated purposes of lesser moment. That certain of these addition products have met with wide acceptance and are considered as valuable adjutants to lubrication is further proof of the deficiencies of highly refined hydrocarbon oils.

It has been the purpose of the studies reported here to determine certain of the chemical and physical changes produced by the addition of selected chemical components to a reference hydrocarbon oil of known low viscosity and to further study the influence of dual additions of corrosion inhibiting and 'corrosive' types of additions.

As a supplement to these studies, corresponding tests have been conducted upon a number of motor oil addition pro-

ducts offered in the American and foreign markets.

The data reported here should be considered as exploratory in every sense. The conclusions drawn in the summary (Section VIII) may be accepted as indicative of the performance of the limited number of molecular components investigated and as guidance for further serious investigation.

SECTION II

HISTORICAL SURVEY

Since the dawn of civilization, mankind has continu-
ally directed its efforts toward the development of machines
and appliances of innumerable types whose purpose it has been
and is to minimize the physical labors required for unit oper-
ations; and to thus elongate the minute, the hour, the day,
the year, and a lifetime by making possible greater accomp-
lishments. Early scientific developments were invariably
dependent upon elementary but fundamental concepts of mech-
anism. The application of these concepts and the urge for
mechanical efficiency has, since the first effort in this
direction, required lubricants whose office is and always
has been to reduce the energy wasted by friction, and to
thus make possible greater productiveness with less and less
effort. These efforts have resulted in the machine becoming
increasingly efficient by virtue of improved design, construct-
ion, and lubrication.

Design and construction are outside the domain of the
chemist, except as his efforts are related to the perfection
of more suitable materials for fabrication. The third re-
quisite of mechanical progress, Lubrication, is distinctly a

chemical problem. As one studies the history of lubrication
it becomes immediately apparent that this adjutant of mech-
anical perfection has been most neglected and continues to
receive sparse attention.

During modern times, improved design and a greater
choice of raw materials from which to construct mechanical
devices and appliances, have made it more and more apparent
to the observant worker that the application of proper lubri-
cants is the difference between success and failure in many
instances. Previous to the discovery and application of
petroleum as a lubricant, animal fats, vegetable fats, shale
oils and other easily available naturally occuring oily sub-
stances were used as lubricants. For many purposes animal
fats and vegetable fats still enjoy wide usage and appear to
give excellent service.

The ever-increasing popularity of mechanical devices
and the far flung applications of machines of innumerable
types has created a demand for lubricants which, in all pro-
bability, could not have been made except for the develop-
ment of the petroleum resources of the world. It has long
been recognized that petroleum lubricants, as used today,
are for many purposes not the equal of naturally occurring
fats and oils. The observation of this fact has led
scientists to give spasmodic attention to the actual prob-
lems involved in lubrication and has resulted in the formu-
lation of numerous theoretical and practical hypotheses upon

which to base further study and from which to gain further practical experience.

It was the purposes of the studies reported in this paper to determine the effects produced when certain chemical bodies of known constitution are added to hydrocarbon oils. A survey of the literature revealed a vast amount of qualitative and descriptive data relating to the action of a limited number of chemical entities. The data reported on those compounds which have been studied was found to be, in most cases, incomplete and of such a nature as to be of little use for the purpose of predicting the relative effects of the chemical components involved.

The technological importance of lubrication is so great that it will sooner or later demand the serious attention of an increasing number of investigators. The work reported in this paper may be considered as wholly exploratory.

SECTION III

THEORIES OF LUBRICATION AND THEIR WEAKNESS

The necessity for lubrication was early attributed to imperfections in rubbing surfaces. The frictional power consumption was assumed to have been caused by the inter-locking of projections on bearing surfaces. This physical inter-locking of surface irregularities was assumed to be the prime cause for the restriction of motion and was held responsible for the losses which occur during the transmis-sion of power through the medium of bearing surfaces. It was, however, soon observed that surfaces which had been lapped to such an extent that physical imperfections were negligible, still offered large resistance to motion. This resistance to motion is so great that surfaces lapped as plain as is possible wear rapidly when moved together with-out the application of a lubricant, thus pointing to the now accepted view that other factors enter into the development of friction.

Corse (1) very clearly reviews the expositions of Cuy-pers (15) and points out that the physical inter-locking of surface irregularities is unnecessary for the development of large values of friction. He further puts forth the possib-ility that an inter-locking of the heterogeneous electromag-

-netic fields of force radiating from surface molecules may, be and probably ~~is~~ responsible for high values of friction under conditions where metal to metal contact exists within the bearing unit. It would further appear that some slight linkage of electromagnetic fields might also exist under conditions of abnormally thin film separation (lubrication). The magnitude of the forces involved in such thin film linkages would, however, appear to be of small moment if it may be assumed that the minimum film thickness is proportional to the thickness of a hydrocarbon molecule. Harkin's (2-A) work indicates that this value should be in the neighborhood of $4.7^{\circ}A$. If the length of an average carboxalic acid molecule approximating the equivalent of an 18 carbon atom chain is taken as 25° A it becomes apparent that the substitution of upstanding molecules of this type would increase the minimum metal to metal separation under conditions of thin film lubrication from $9.4^{\circ}A$ to $50^{\circ}A$. This increase in minimum film thickness would in any event reduce the effectiveness of electromagnetic linkages as the square of the separation distances, or as 88 to 2500. This would reduce the electromagnetic field intensity to 0.035 of its original value. The increase in coefficient of friction with increased bearing pressure may be at least partially dependent upon this consideration.

Engineers classify lubrication films according to their thickness. So-called 'thick film lubrication' prevails under those conditions where bearing tolerances are sufficiently large to permit a thick coating (multi-molecular) of lubricant on both journal and bearing surfaces. With this type of lubrication, it would appear that the constitution of the lubricant has little to do with the efficiency of lubrication and that the only factor of importance is the viscosity of the lubricant. Accordingly, bearings operated under conditions of large clearance are lubricated with oils of high viscosity. So long as unit pressures remain sufficiently low to enable the film of lubricant to be maintained, metal to metal contact cannot exist and it would be surmised that the electrostatic linkages considered in connection with thin film lubrication would be a factor of small moment.

The second type of lubrication is known as 'thin film lubrication'. It is of this state that the present studies relate. Thin film lubrication is considered of great importance because it may be encountered under emergency conditions even in equipment designed for lubrication with high viscosity oils. It is known that metal contact actually exists under certain conditions even on machines lubricated with very high viscosity oils.

Thin film lubrication prevails when sudden changes in

motion occur, when sudden pressures are applied to the bearing-supported mechanisms, when gear teeth mesh under load, at the point of contact of cutting tools, and between parallel surfaces rubbing under such conditions as exist between pistons and cylinder walls in engines of all types, compressors, and other mechanically similar units.

At the moment of transition from thick film lubrication to thin film lubrication, it has been observed that the tangental friction drag per unit area increases rapidly. Under the conditions of thin film lubrication, it has been known for many years that a factor commonly termed the 'oiliness' of the lubricant becomes important. In order to be effective, under the conditions of thin film lubrication, a lubricant must possess the property of completely wetting the metal surfaces, spreading into a thin film, and maintaining itself in this condition even though great strains are applied.

Cuypers (15) defines 'oiliness' as the sum of the phenomena which tends to maintain a lubricating film under the influences of the solid surfaces, and decreases friction without generating fluid friction, within the lubricant itself, in excess of the reduction effected between the metals. He further states:

> "While with complete film lubrication the
> viscosity is the factor which causes the
> decrease in friction, the cause of reduct-
> ion in friction in the case of complete

film lubrication, is not the viscosity
but the 'oiliness' of the lubricant.''

As reported by Corse (1), Woog (28,29,30), has investigated the factors upon which good oiliness relies and has suggested a method for accomplishing this. The following four paragraphs are quoted direct from Corse's summary of Woog's papers:-

1. '' The mutual keying together of the molecules of the lubricant, by which we understand the resistance they oppose to pulling apart, insofar as it depends on a single molecule's having a hold on its neighboring molecules. For this hold, the size of the molecular volume of a lubricant, so much firmer does it hold even the thinnest film together. ''

2. ''The form and dimensions of the lubricant molecule: we should not imagine the molecules as symmetrical, spherical shapes, but as more complicated forms showing strong irregularities. An oil film which consists of long molecules which stand close together like the bristles of a brush is much more resistant to the tendency of rotation than is an oil film consisting of molecules more nearly spherical. ''

3. ''The presence of specially active centers of energy in certain molecules, which forces them under certain conditions to take on quite different positions: especially effective are such centers of energy when they are located at the end of the molecule. It appears that the durability of the oil film standing in direct contact with the solid surfaces will be so much the greater the firmer the lubricant molecules anchor themselves to the surfaces. And this anchoring will always be especially intensified if the force of attraction due to the metal surfaces themselves is strengthened by a special affinity of the lubricant molecules in which even such active centers of energy orient themselves toward the surfaces.''

4. ''The fourth factor of oiliness of a lubricant is the elastic stiffness of its molecules.''

In view of the data reported in this paper, together with other data which the writer has had an opportunity to study, it appears that the following comments to the above four points as put forth by Woog are subject to criticism as follows:

1. Woog's theory would indicate that the film of lubricant is to be considered as an extremely thin sheet or film between the bearing and shaft and that it is in no wise influenced by the metals from which the bearings and shaft are constructed. Accordingly, he holds that **the molecular volume is the important** consideration.

The writer favors the theory that the dimensions of the molecules **composing the lubricating medium are of relatively no consequence** and that instead some factor equivalent to inter-molecular bonding is of greater importance. By this is meant, that assuming a continuity of the moving film, the factors which would make a film difficult to rupture would require strong bonding between consecutive molecules making up the mobile film.

Woog's theory does not sufficiently emphasize the importance of oriented molecular entities on the faces of the bearing and shaft. This appears to be a fatal weakness to the theory which could only be surmounted by assuming the presence, in the lubricant, of certain **mole**cules which tend to orientate themselves on the metal

surface to be lubricated and thus exert a smoothing out action on the surface itself. The smoothing out effect is suggested in view of the fact that the best lapped surface may still contain crevices, ridges, depressions and other irregularities whose amplitude can be as much as 70° to 80°A. from the crest to valley. In practice the amplitudes may be many times greater. Carboxylic acid molecules containing 18 carbon atoms per chain are considered to be in the neighborhood of 20° to 25° A. in length. If we assume that molecules of carboxylic acids orient themselves on the surface of the metal with the carboxyl group at the metal interface, it is apparent that under ordinary conditions we should expect that the maxima and minima of surface variation would become much less than 80° A. and would more nearly approach the length of the carboxylic acid molecule. If this is the case, then the presence over the entire bearing surface and shaft surface of oriented carboxylic acid molecules would tend to limit the surface variations to substantially 20° or 25° A. units in the case of carboxylic acids containing substantially 18 carbon atoms per molecule. The case of substituted and unsaturated carboxylic acids merits further consideration and its effects will be discussed at length with the data pertaining to tests on their performance.

    2.   In Woog's second requirement as detailed above, it

is indicated that the shape of the molecule is of considerable importance in determining its fitness as a lubricant. The suggestions put forth appear logical if we interpret his statements as referring to those molecules which form the thick film layer between the hydrocarbon tails of oriented carboxylic acids. On the basis of his statements, we would be led to the conclusion that open chain aliphatic hydrocarbons would in all cases be superior as thick film lubricants to cyclic hydrocarbon molecules. This appears to be borne out in practice, inasmuch as paraffinic oils are generally considered superior to naphthenic lubricants.

3. In Woog's third qualifying paragraph, he brings out the importance of certain types of Polar groups which show a tendency to 'anchor' themselves to the metal surfaces. In this connection, the findings reported here tend to emphasize the importance of Polar groups and to further indicate the nature and limit the location of those Polar groups which are most effective. At this point, it should be mentioned that it does not appear desirable that lubricants contain unstable Polar groups which upon decomposition, addition to or substitution into, can give rise to the formation of groups which would attack the bearing metals. Furthermore, it is indicated that the presence of chemical groups in the lubricant which exert a corrosive action upon bearing or shaft is of considerable importance in selecting the type of carboxylic acid molecule which will be most

effective. It will later be shown that the presence of
oleic acid in the proportions of not to exceed 1% and pro-
bably in lesser percentages, inhibits the corrosive act-
ion of certain phosphoric acid esters to the extent of 80%
while it is not only ineffectual but actually accelerates
the corrosive action of phenyl chloride. In other words,
an oil containing a trace of phenyl chloride is made more
corrosive and more destructive to bearing surfaces and shafts
by virtue of the presence of oleic acid. This would suggest
the possibility of substitution at the double bond in oleic
acid by the degradation products of the phenyl chloride
molecule.

4. The statement above that the fourth factor of oili-
ness depends upon the elastic stiffness of the molecules
present is not entirely clear. This statement may be inter-
preted as referring to the presence or absence of double
bonds in the lubricant molecule. If we assume this inter-
pretation, then this qualification becomes entirely in ac-
cord with present findings, provided we further restrict
this 'molecular flexibility' to the molecules which orient
themselves upon the surface of the metals being lubricated.
By the methods used in this investigation, it has not been
possible to determine the comparative effectiveness of
olefines and saturated hydrocarbons as filler lubricants
which operate between the oriented boundaries.

Wilson and Bernard (27) have proposed a definition for 'oiliness'. Their definition follows: 'Oiliness is defined as that property of lubricants by virtue of which one fluid gives lower coefficients of friction (generally at slow speeds or high loads) than another fluid of the same viscosity'. With deference to the incompleteness of the Bernard definition, particularly with respect to its omitting the problem of film rupture, strength, Burwell and Camelford (13) have proposed that the Wilson and Bernard definition should be revised to read: 'Oiliness is defined as that property of lubricants by virtue of which one fluid gives lower coefficients of friction (generally at slow speeds or high loads) than another fluid of the same viscosity and at the same time increases the film strength of such lubricants.'

The data reported here would indicate that if the definition for oiliness as suggested by Bernard and Wilson is to be modified along the lines suggested by Burwell and Camelford, that it should be further modified in such a manner as to definitely eliminate, limit, or specify the classification of film strength desired. As a result of the work reported here, it has been found advisable to classify film strength enhancing addition agents according to the mechanism by which the increase in film strength is produced.

Unsubstituted carboxylic acids, when added to hydro-
carbon oils relatively free from olefines and unstable
chemical molecules have been shown to definitely increase
the film strength of the lubricant without effecting the
corrosion of the metals making up the bearing and shaft.
Furthermore, it has been found that the addition of certain
phosphoric acid esters, halogenated compounds, sulphur com-
pounds and certain other molecular components to be discussed
in detail later, increase the film strength of the lubricant
in many cases far above the values which have been realized
to date from carboxylic acid additions; however, this increase
in film strength has been attended with rapid corrosion and
erosion of bearing metal and shaft.   It has been further
observed that the addition of certain types of carboxylic
acids to oil samples carrying corrosive film strength im-
proving molecules either completely inhibits the corrosion
or only partially inhibits the corrosion. When corrosion
is completely inhibited, the film strength of the complex
is reduced to the value originally produced by the particular
carboxylic acid alone.   In those cases where corrosion has
been only partially inhibited, the film strength of the lub-
ricant was found to be reduced to a value intermediate be-
tween that produced by the carboxylic acid alone and the
corrosive agent alone.   This points to the conclusion that
molecular components which improve film strength by virtue

of their corrosive action can only be inhibited from corroding by the addition of molecules which have the property of orienting themselves on the surface of the metals to such an extent as to preclude contact of the corroding addition.   In these cases, the film strength is, as would be expected, reduced to the value produced by the inhibitor alone. This points to the fallacy in attempting to use corrosive additions for the purpose of promoting film strength and adding with them inhibitors to overcome their deleterious effects.

Persuant to these views, it would appear that a further revision of the definition of oiliness should be made as follows: Oiliness is defined as that property of a lubricant by virtue of which one fluid gives lower coefficients of friction (generally at low speeds or high loads) than another fluid of the same viscosity and at the same time increases the film strength of such lubricants without causing corrosion to bearing surfaces and without promoting corrosion by any components which may be present under the conditions imposed upon the lubricant in use.

SECTION IV

LABORATORY PROCEDURE

For the purpose of this investigation a quantity of highly refined mineral oil of paraffinic origin was procured. The lubricant used was found to have a viscosity of 85 sec. at 100° F. (Saybolt Universal). This oil was tested and found to have a comparatively low lubricating value, a quality considered desirable for the purposes, inasmuch as it was desired to determine the effects of certain molecules and combinations of molecules upon the lubricating quality and film strength characteristics of hydrocarbons.

Samples of the above oil were made up, each containing 3% by volume of the following:

Table A

Phenyl Chloride	Tricresyl Phosphate
Alpha Chloronaphthalein	Butyl "Carbitol"
Triamylamine	Lauric Acid
"Alketoacid" C-18	Butyl Lactate
Ricinoleic Acid	Isopropyl Ether
Triethanolamine	Trioxymethylene
Linoleic Acid	Dibutyl Phthalate
Palmitic Acid	Pine Needle Oil
"Alketone" C-32	Thymol

"Alketone" C-20   Benzaldehyde

Stearic Acid   Oleic Acid

Undecylenic Acid

Samples were also prepared as follows:

	A	B	C	D
White Oil	99%	98%	96%	94%
Oleic	1	2	4	6

	E
White Oil	94%
Oleic Acid	3
Phenyl Chloride	3

Samples containing mineral oil to which was added tri-
cresyl phosphate, 3%, and the following components were also
prepared for the determinations discussed in Section VII.

Table C

Oleic Acid	1%	"Alketone" C-18	3%
Oleic Acid	2	Palmitic Acid	3
Oleic Acid	3	Ricinoleic Acid	3
Oleic Acid	4	"Alketone" C-20	3
Oleic Acid	6	"Alketone" C-32	3

TEST METHODS

An adsorption dynomometer of the Faville LeVally type
was used in accordance with the procedures herein described

for the conduct of the tests reported. It was found necessary to make certain modifications in the standard Faville LeVally machine in order to render test runs reproduceable. Fig. 1 which follows shows the assembly arrangement of the Faville LeVally machine. It will be noted that a pair of pincher arms press the pair of bearings, of types detailed in Fig. 3 against a 1/4 inch drilled rod shaft under spring tension. The draw-up wheel shown in Fig. 1 and 4 is automatically rotated to bring about a continuous and regular application of pressure increments. The automatic draw-up arrangement was actuated by an eccentric driven by the upper portion of the main bearing shaft. The rate of pressure increments was, therefore, 1 notch per shaft revolution, or 290 notches per minute. Each notch on the take-up wheel corresponded with a bearing squeeze on the shaft produced by 0.000067 inches of spring compression. The dynomometer unit was driven by a synchronous motor to maintain constant speed throughout all tests.

When the test operations were initiated, it was hoped that the construction of the machine would permit the measurement of oil film thickness by comparing the calibrated take-up wheel indications with a previously run pressure curve. Accordingly, a calibration run was made with hardened steel bearings of the type shown in Fig. 3A pressed against a drill rod shaft without lubrication. A large number of tests were made to determine the relationship between take-up wheel calibration and

applied pressure as indicated on the pressure gauge. Curve 1 attached indicates the variation which was found to occur in repeat runs. The heavy line is plotted to the average of all calibration tests conducted. In view of the cyclic variations in the notch-up to produce a given pressure, all hope of measuring film thickness by this method was abandoned. The limit curve showing the relation between notch-up and pressure, however, has been retained in curves, in order to give some idea of the probable change in oil film thickness under conditions of increasing pressure.

INTERPRETATION OF DYNOMOMETER DATA

In computing comparative values discussed, the following symbols have been used uniformly. Consideration of these values together with the diagrams appended is included to make clear the performance of the test equipment.

r_k = radius of shaft = .125 inches.

d_k = distance between center of shaft and point of contact between torque arm and sylphon tip.

f_1 = force tangental to shaft.

f_2 = force applied to sylphon gauge by torque arm.

t = moment of torque developed by friction in pound inches.

d_1 = length of pressure application arm (total).

d_2 = distance between pressure arm fulcrum and shaft center.

P = gross pressure on bearing faces.

CURVE I
CALIBRATION OF TAKE-UP WHEEL

PRESSURE (Lb's)

The bearing faces pressing against the surface of the shaft (Fig. 1 and 2) produce a frictional force which tends to cause the bearings to rotate with the shaft. These forces may be resolved into a single force acting tangental to the surface of the shaft. The product of this resolved frictional force times the radius of the shaft represents the moment of torque developed by friction.

$$(1) \quad t = r_k \text{ X } f_1$$

This torque, which tends to produce rotation of the bearing unit, is counter-balanced by the moment of the torque arm pressing against the tip of the pressure gauge sylphon.

The moment of this torque arm is equal to the product of the distance between the center of the rotating shaft and the point of support of the torque arm on the sylphon tip, and the force acting on the fluid filled sylphon as indicated by the Bourdon type of gauge actuated by the sylphon or:

$$(2) \quad t = d_k \text{ X } f_2$$

Equating 1 and 2 gives an expression for the force tangental to the bearing shaft.

$$(3) \quad r_k \text{ X } f_1 = d_k \text{ X } f_2 \text{ or}$$
$$f_1 = \frac{d_k \text{ X } f_2}{r_k}$$

Frictional power consumption is most readily calculated in horsepower from the English system calibration of the machine, by multiplying frictional torque times radians per

minute and dividing by 33,000 or:

$$(4)\ \text{Frictional H. P.} = \frac{2\pi t\ (\text{R.P.M. of shaft})}{33,000}$$

$$(5)\ \text{Watts consumed by friction} = \text{H. P. X 746}$$

In order to compare the friction rates at the various test pressure applied, the following coefficient was used:

$$(6)\ \text{Torque coefficient} = \frac{t}{P}\ \text{X 100}$$

This coefficient was selected because torque is proportional to frictional power consumption and it was found helpful to evaluate repeat runs on the basis of this coefficient in determining the validity of the tests in question.

OPERATING PROCEDURE

The film strength tests reported in Sections V and VI were conducted on hardened steel bearings of the types shown in Fig. 3A and 3B as indicated. The shaft consisted of a hardened section of polished drill rod. In all cases, both shafts and bearings were lapped to a good polish.

Previous to each test, the machine was thoroughly washed, first with naphtha and then with trichlorethylene to remove the last trace of impurity from previous tests. The clean bearing halves and shaft were then installed in the machine and the pressure jaws applied loosely. The oil container was filled with its standard (70 cc.) charge of oil, the machine started, and the pressure wheel slowly drawn up to a gross pressure of 250 pounds. At this instant, the time clock was started and

the machine allowed to operate for three minutes. This initial three minutes was considered as a break-in period, whose function it was to allow the bearing faces to properly align and to remove any slight surface irregularities which might exist. In all cases, torque and pressure were stabilized within the first few seconds of operation and remained constant throughout the three minute break-in period. At the conclusion of the break-in period, the automatic draw-up mechanism driven by the eccentric was thrown into communication with the notched draw-up wheel and allowed to apply pressure automatically until the pressure as indicated by the gauge had reached 500 pounds. At this point the automatic notch-up mechanism was removed for 5 seconds while notch-up values and torque readings were taken. The notch-up arrangement was immediately replaced and allowed to continue until the pressure had been increased by another increment of 250 pounds. This procedure was repeated uniformly until bearing seizure or excessive wear occurred. In all cases, the final torque value was recorded regardless of whether the test was run to seizure or to excess wear.

The tabular data reported in Section IX reports all values taken in the following units:

      t = Torque in Pound Inches.

      P = Pressure in gross pounds of pressure applied to bearing face.

      n = Notch-up or take-up in number of notches actually taken up during pressure interval.

The constant pressure wear tests reported in Section VII in connection with commercial products were made according to the following procedure:

Bearings of the type shown in Fig. 3C were accurately machined to a depth of .075 inches and to a curvature corresponding with a 1/4 inch diameter shaft. The shaping of these bearing faces was effected in a specially constructed fixture to insure uniformity. These bearings were then run in to produce a satisfactory test surface.

The above described bearings were drilled at a uniform distance below the bearing surface (in a fixture) and an iron constantine thermo-couple was installed for the purpose of temperature recording.

The above bearings, equipped with thermo-couples were installed in the test dynomometer. After installing the bearings, the pressure was brought to 10 lbs. and the machine started. The pressure was immediately increased to a gross pressure of 50 lbs., and a running 5 minute break-in period allowed to insure suitable bearing linement and normal machine operation. At the end of the break-in period, readings of notch-up wheel, temperature, torque, and pressure were taken. For the remaining period of the test, the pressure arrangement was adjusted at one minute intervals to maintain a uniform pressure of 50 lbs. gross. Readings of temperature, torque, and wear were then taken at 5 minute intervals throughout the

duration of the test.

FILM STRENGTH TESTS ON COMMERCIAL PRODUCTS

The film strength tests reported in Section VII were conducted on hardened steel bearings of the type shown in Fig. 3B. These bearings were carefully lapped to a highly polished surface and the tests conducted in a manner similar to the V-bearing seizure tests detailed above.

After a 5 minute break-in period, the automatic ratchet take-up mechanism was allowed to operate until the pressure had increased to 250 lbs. The machine was allowed to operate for 5 minutes at this pressure, after which readings of temperature, and torque were taken. The machine was immediately notched up by automatic feed for an additional increment of 250 lbs. and operation allowed to continue for 5 minutes, after which readings were taken. This procedure was continued until seizure occurred.

ADDITIONAL LABORATORY PROCEDURES

Additional laboratory procedures resorted to in the course of gathering the data reported herein will be discussed in the various sections involved.

SECTION V

CARBOXYLIC ACIDS, NEUTRAL SUBSTITUTION PRODUCTS, ALIPHATIC HYDROCARBONS ESTERS

A total of 12 derivatives consisting of saturated and unsaturated carboxylic acids, hydroxy carboxylic acids, ketone alcohols and keto hydroxy carboxylic acids were examined with the adsorption dynomometer described in Section IV. The following is a summary of the seizure pressures and corrosion observations in connection with these tests:

TABLE D

Compound	Detailed Test Data in Table	Seizure Pressure	Corrosion
Reference Hydrocarbon	I	750 lbs.	None
'Alketoacid' C-18	VII	1500 lbs.	None
Oleic Acid	II	1250 lbs.	None
'Alketone' C-32	XIII	1250 lbs.	None
Palmitic Acid	XII	1250 lbs.	None
Linoleic Acid	XI	1250 lbs.	None
Butyl Lactate	XXI	1250 lbs.	None
Undecylenic Acid	XVI	1200 lbs.	Slight corrosion
Stearic Acid	XV	1200 lbs.	Solubility low- no evidence of corrosion

TABLE D. Continued:

Compound	Detailed Test Data in Table	Seizure Pressure	Corrosion
Ricinoleic Acid	VIII	1175 lbs.	None
Pine Needle Oil	XXIII	1100 lbs.	Slight corrosion
'Alketone' C-20	XIV	1000 lbs.	None
Lauric Acid	XIX	900 lbs.	None

In reviewing these data, the following characteristics are significant.

(I) The carboxylic acids and the ester tested were found to be non-corrosive to the steel bearings under the test conditions prevailing. The one exception is in the case of the undecylenic acid. The sample of undecylenic acid used was made by the destructive distillation of castor oil and accordingly contained impurities difficult to remove and which may possibly have been responsible for the slight corrosion which was observed. This opinion is borne out by the fact that other carboxylic acids containing a double bond did not produce corrosion.

(2) The carboxylic acids having long carbon chains group themselves close together with respect to seizure pressure.

(3)   The carboxylic acid which required the greatest
pressure before seizure occurred contains alpha, beta and
gamma hydroxyl and carbonyl groups.   In view of the fact
that this particular carboxylic acid is made by the oxida-
tion of petroleum fractions, it was not found practical to
separate it into fractions of known molecular constitution,
however, it is definitely known that two or more hydroxyl
and carbonyl groups are substituted in the positions afore-
mentioned.   In view of this information and the seizure
performance of the oil sample containing this material, it
would appear that the orientation of the molecule at the
metal interface involves a stronger bond.

        To gain further information relative to the nature
of the above indicated increase in seizure pressure, a
series of tests were run with oleic acid additions in in-
creasing quantities to the reference hydrocarbon oil used
throughout these tests.

        The following table records the significant values
observed in connection with these tests:

TABLE   E

Oleic Acid Concentration Tests

	1%	2%	3%	4%	6%
Seizure Pressure	1250	1250	1250	1250	1500
Seizure Torque	80	80	85	90	90
$\dfrac{t \times 100}{P}$	6.4	6.4	6.8	7.2	6.0

In view of the fact that the seizure pressure was practically constant regardless of oleic acid concentration, it would appear that within the limits required to produce complete molecular orientation over the entire surface to be lubricated additional quantities of oleic acid have no function. The seizure torque values show an upward trend; however these values are well within the limits of experimental error. This fact is occasioned on account of the rapidity with which seizure occurs and the attendant difficulty in taking a maximum reading. The variation in torque coefficient values reflect this torque uncertainty.

The data shown in Table D relative to the performance of carboxylic acids and that shown in Table E relative to the concentration performance of a typical carboxylic acid points definitely to the conclusion that the improvement in film strength produced by carboxylic acids is due to the formation of an oriented film of carboxylic acid on the metal surface.

A further consideration of this view suggested the possibility of studying the heats of wetting of carboxylic acids in contact with metals. Due probably to the low values of heats of wetting, only a few investigators have studied this value.

The work of Breiger (12) was found to contain data on the heats of wetting of castor oil, linseed oil, paraffin

oil, refined machine oil, and oleic acid 1% in petroleum oil on copper.

Previous work by Crowley (14) indicates that tri-glycerides of fatty acids are ineffectual in reducing seizure values and torque values unless free carboxylic acid is present. Accordingly, the work of Breiger (12) was interpreted as indicative of the heat of wetting for the carboxylic acids corresponding to the tri-glycerides reported. This assumption is considered reasonable in view of the known fact that unless special precautions are taken, a sufficient quantity of free acid always exists in tri-glycerides to give concentrations well within the limits of that required to orient themselves on the metal surfaces under the test conditions reported by Breiger.

Assuming that Breiger's values apply to the carboxylic acids which would be present in castor oil and linseed oil, the following corrected values for heats of wetting in degrees Centigrade per 100 grams of copper adsorbent were tabulated.

	Heat of Wetting	Seizure Values found here
Oleic Acid 1% in unknown mixture	21.25° C	1250
Linseed Oil (Linoleic Acid)	13.85	1250
Castor Oil (Ricinoleic Acid)	12.07	1175
Paraffin Oil	3.85	750

It is significant to note that these values for
the heats of wetting and seizure values as determined by
the methods used in this study, agree in order; and further
that the ratio of the heat of wetting of linseed oil (13.85)
to that of castor oil (12.07) equals 1.09, while the ratio
of the seizure pressure of Linoleic acid (1250 lbs.) to that
of Ricinoleic acid (1175 lbs.) equals 1.065.   The agree-
ment in this one particular case is considered extremely
close in view of the difference in the methods used.

Breiger's value for the heat of wetting of oleic
acid was determined in a petroleum solution of undefined
composition and therefore it would hardly be expected that
his value for oleic acid would be comparable to the other
values reported.

The property known as lubrication has been defined
by Dallwitz (16) as being proportional to the ease with
which the oil is adsorbed by the metal.   He states that
the tenacity of the oil film would appear to depend upon
the capillary properties of the oil and the metals to be
lubricated. Dallwitz- Wegener (17) have outlined a series
of methods whose purpose it is to make possible the deter-
mination of these values. Pursuing the above citations in-
dicates that these investigators believe that the lubri-
cating power of an oil increases and decreases with changes
in its angle of contact with the metal.   Their conclusions
indicate that the lower the surface tension of a lubricant,

the better will it be expected to perform its function.

In view of these findings, it would appear that the metal surface being lubricated acts as an adsorber and therefore the oil constitutes the adsorbent. Breiger suggests that this adsorbing function of metallic surfaces may be the result of residual valencies of the atoms on the surface. He further adds that adsorption therefore consists in saturating these valencies with the secondary valencies of the adsorbed molecules. He then goes on to define the heat of wetting as the heat liberated during adsorption.

The work of Southcomb and Wells (24) indicates that exceedingly small quantities of unsaturated groups produce extraordinary increases in the lubricating ability of poor oils.

Wells and Southcomb (24) have also found that the glycerides of fatty acids possess lower surface tensions than do hydrocarbon oils. They further show that the reduced surface tension of triglycerides is attendant with the presence of free fatty acids. They further show that the surface tension of natural glycerides, free from fatty acids, are of the same magnitude as the surface tensions of mineral oils. They further give evidence to the effect that the lubricating power of either natural glycerides, free from fatty acid, or a hydrocarbon oil is greatly enhanced by addition of a small percentage of fatty acids. Wells (24A)

shows that oleic acid forms an oriented film on metal surfaces which has a thickness of 4×10^{-7} cm.

In view of the findings reported here and additional data recorded in the literature, it would appear that increase in film strength of the lubricant and reduction in friction is effected to the greatest extent when molecules are present which have the property of forming an oriented layer on the surface of the metals to be lubricated. It would further appear that oxygen-containing groups, hydroxyl and carbonyl, are most effective. It cannot be inferred that the presence or absence of double bonds in the added molecules are of any more than pure physical significance. The effectiveness of oxygen in this respect is attested to by the findings of Gilson (18). In his investigations, a machine was arranged so that the bearing being lubricated could be operated in controlled gaseous atmospheres. This procedure was followed pursuant to results from certain previous tests, which had appeared to have been affected by the presence of gaseous components present in the atmosphere surrounding the test equipment. The following quotation is taken from Gilson's work:
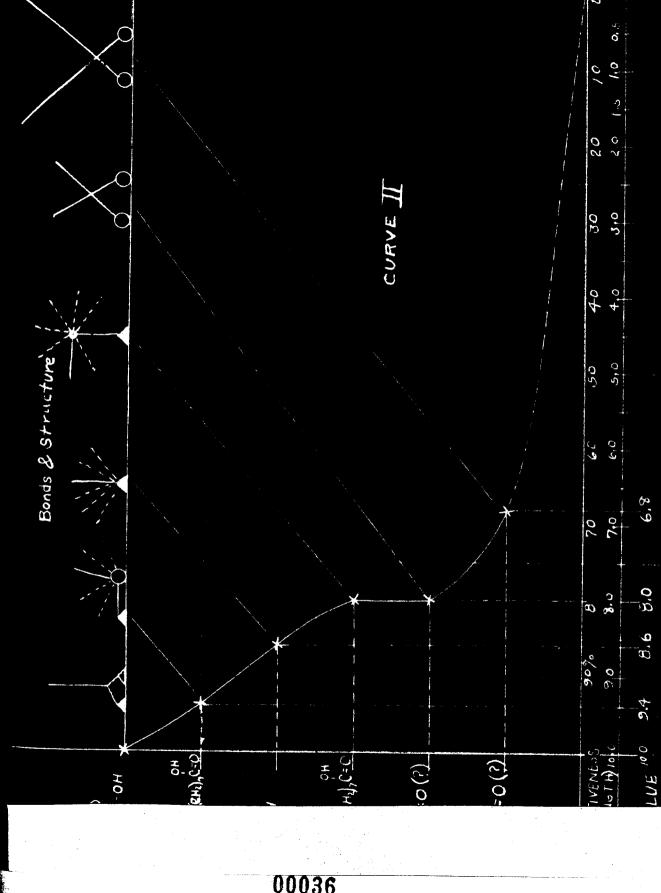

> " A small bearing was mounted so that tests could
> be made on it while running in any atmosphere.
> The friction in a vacuum was much higher than
> in air. Oxygen gave lower friction than air;
> if the oxygen was exhausted the friction increased but not to the original value for a
> vacuum. The bearing was run continuously in   "
> a vacuum and readings taken at 8 hour intervals.

" The friction became progressively higher, and
had not reached a maximum at the end of test.
If the bearing was then run in air for 8 hours the
friction dropped almost to its original value in
oxygen. Moisture was also found to have an effect,
the friction being much less in moist than in dry
hydrogen."

    "The experiments indicate that for efficient
lubrication some kind of reaction is necessary
which is dependent upon the presence of moisture
and of oxygen. The fact seems to be well estab-
lished that the surrounding atmosphere has a very
decided effect upon the friction obtained. The
differences in friction cannot be accounted for by
differences in viscosity of the oil. All of the
friction curves tend to come together in the region
around 100°C., but it is not yet known whether or
not this has any significance."

    Further conclusions indicated, from the tests con-
ducted will be discussed in Section VIII in deference to
further data reported in the following section.

    The attached Curve II presents in curve form the
comparative performance of the group members reported in
this section together with a diagramatic illustration of
the suggested bonding at the metal interface and the
writers interpretation of the influence of double bonds.

SECTION VI

TESTS WITH AROMATIC HALIDES AND OTHER MOLECULAR COMPONENTS

A total of 15 chemical compounds were added to the reference hydrocarbon oil in the proportions of 3% by volume and tested under conditions identical to those discussed in Section IV. The following table summarizes these findings with respect to seizure pressure, and corrosion.

Table F

Compound	Detailed Test Data In Table	Seizure Pressure	Corrosion
Reference Hydrocarbon	I	750 lbs.	None
Tricresyl Phosphate	XVII	2000	Corroded
Phenyl Chloride	III	1500	Corroded
Benzaldehyde	XXV	1300	Corroded
Alpha Chloronaphthalein	V	1250	Corroded
Dibutyl Phthalate	XXII	1100	Slight Corrosion
Triamylamine	VI	1000	Slight Corrosion
Triethanolamine	IX	1000	Slight Corrosion
*Butyl Carbitol	XVIII	1000	None
Thymol	XXIV	950	Very Slight Corrosion
Isopropyl Ether	X	750	None
*Trioxymethylene	XX	550	Corrosion

* Not completely soluble.

With the exception of sulphur compounds, the above series of tests included all of the commonly used extreme pressure addition products. It is to be noted that in all cases the chemical additions which produced notable improvement in the film strength of the lubricant also corroded both bearing and shaft.

In the case of the first four items listed above, the corrosion was severe. Phosphoric acid esters and chlorides are recognized as important components in extreme pressure lubricants. That these components are corrosive is also well understood.
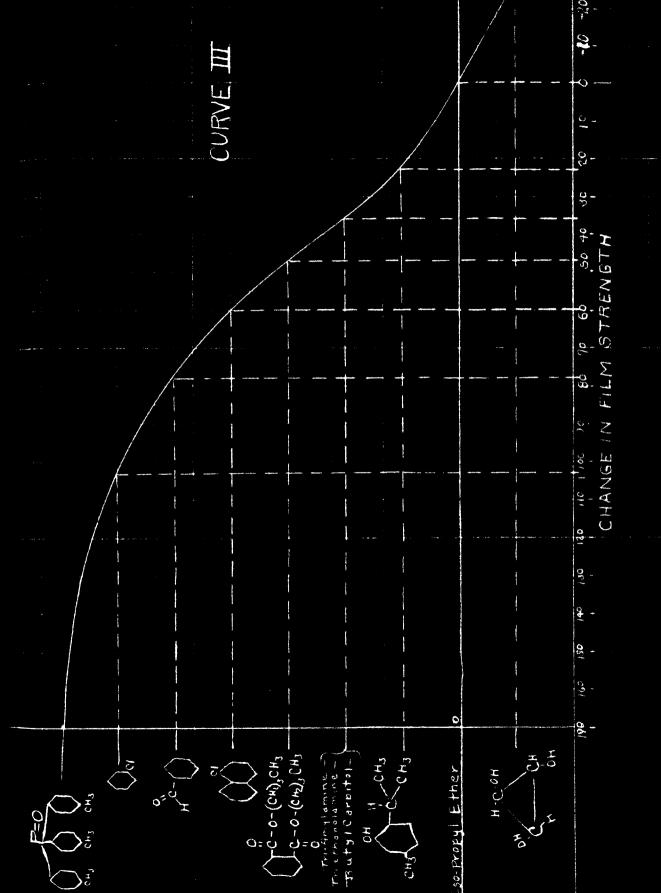

These tests were conducted largely for the purpose of determining the relative corrosiveness and effectiveness as extreme pressure lubricant addition materials with a view of gaining information which could be used for purposes of comparison when non-corroding seizure pressure increasing components were added together with them.

Curve III attached indicates the general performance of these addition products with respect to their effects in seizure pressure.

Further discussions of these data will be contained in Section VII which follows.

TESTS ON PRODUCTS SOLD IN AMERICAN AND FOREIGN MARKETS

Samples of products sold in the American and foreign

CURVE III

CHANGE IN FILM STRENGTH

markets were procured and tested to determine their comparative actions when added to motor oils of standard quality.

These samples are identified by letters as follows:

Table G

	Source	Class	Data In Table
Reference Oil	American	--	XLI
A	American	BB	XLII
B	Foreign	AA	XLIII
C	Foreign	BB	XLIV
D	American	AA	XLV
E	American	BB	XLVI
F	American	EE	XLVII
G	American	EE	XLVIII
H	American	DD	XLIX
I	American	FF	L
J	Foreign	CC	LI

A summary of the test values from this series of tests is shown in the following table.

Table H

SUMMARY OF WEAR, TORQUE, TEMPERATURE RISE
AND BEARING CORROSION VALUE
(Commercial Samples)

Product	Wear	Torque	Condition of Bearing	Temperature Rise
Plain Oil Only	100%	100%	Corroded	100%
A	Reduced 20.5%	Reduced 4.4%	Badly Corroded	Reduced 4.8%

Table H (continued)

Product	Wear	Torque	Condition of Bearing	Temperature Rise
B	Increased 100%	Reduced 15%	Corroded	Reduced 33.3%
C	Increased 3.9%	Reduced 15%	Badly Corroded	Reduced 21.3%
D	Increased 23.6%	No reduction or increase	Badly Corroded	Reduced 14.1%
E	Increased 4.7%	Reduced 13.1%	Corroded	Reduced 12.9%
F	Reduced 40%	Reduced 43.5%	Corroded	Reduced 44.5%
G	Reduced 5.5%	Reduced 27%	Corroded	Reduced 33.3%
H	Reduced 35.4%	Reduced 23.6%	Badly Corroded	Reduced 24.6%
I	Reduced 50%	Reduced 34.7%	Not Corroded	Reduced 31.7%
J	Reduced 17.7%	Reduced 21.7%	Corroded	Reduced 36.5%
Greatest Reduction	I - - - -	F - - - - - -	I - - - -	F

To throw light on the components present in these products, to which may be attributed their characteristic actions, the following table has been prepared. The class letters correspond with the classifications noted in Table H.

Table I

| Class of Product	Composition	Notes	Samples Tested and Identification
AA	Graphite only - High Concentration	Graphite settled rapidly	D and B
BB	Graphite only - Lower Concentration	Slight settling of graphite	A, C and E
CC	Graphite and Animal Oil	Graphite settled due to acidity of fat	J
DD	Graphite and Chemicals	No settling of graphite	H
EE	Chemical additions - No graphite	Acid after test	G and F
FF	Graphite and Hydro-carbon Derivative	No settling of graphite. No acidity after test.	I

At first glance, the greatest improvement in lubricating conditions would appear to rest between sample F and I. In view of the fact that under the test conditions prevailing an increase in wear rate would bring about greater reductions in pressure between the one minute take-up periods, it would be expected that F, which permitted higher wear than I would show a lower torque value and a lower temperature rise than I. Consideration of this factor, together with the entire absence of corrosion on the bearings and shafts lubricated with I, as shown by the photomicrographs removes all doubt as to preference.
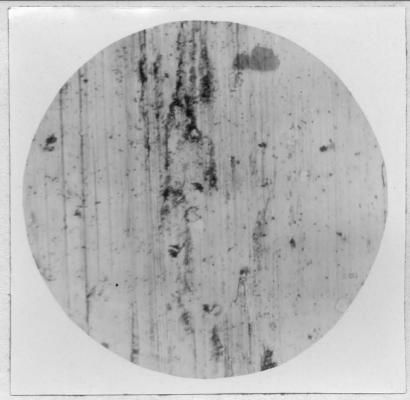

Unused sample of Product I (uncon-
fined).   Magnification - 125 X.

Unused sample of Product I (confined
under cover glass).   Magnification
125 X.

Photomicrograph of Copper Lead type
bearing used in Test No. LV. Evidence
of chemical attack is apparent.
Magnification - 125 X.

Photomicrograph of Copper Lead type
bearing used in Test No. LVI. Chemical attack is not indicated.
Magnification - 125 X.

Photomicrograph of Cadmium Silver
type bearing used in Test No. LII.
Chemical and mechanical attack of
the bearing surface is indicated.
Magnification - 125 X.

Photomicrograph of Cadmium Silver type
bearing used in Test LII-A. The practi-
cal absence of chemical attack is indi-
cated, showing effectiveness of inhibi-
tors present. Magnification - 125 X.

Photomicrograph of steel shaft from
Test LII. Corroded bearing alloy has
been imbedded in the shaft.
Magnification - 125 X.

Photomicrograph of steel shaft from
Test LII-A. The surface is practi-
cally free from bearing metal and
corrosion inclusions, indicating
that inhibitors present have pre-
vented both contact and corrosion.
Magnification - 125 X.

Photomicrograph of oil from Test
No. LII. Large particles of metal
as shown were found to be present
in considerable quantity. Magnifi-
cation 125 X.

Photomicrograph of oil from Test
No. VII-A. The low concentration
of metal particles and their small
size indicates that tearing has been
minimized. Magnification - 125 X.

A study of these data indicates that the presence of colloidal graphite in lubricating addition products is desirable if it is present in suitable form and concentration.

To gain further information on the function of colloidal graphite, a series of tests were conducted with lubricants containing product I. The base lubricants to which this product was added ranged in viscosity from 10-W to S.A.E.-50. The oils selected for these tests consisted of standard grades of lubricating oils of paraffinic, mixed, and naphthenic origin.

For one of these tests, the colloidal graphite was removed from sample I by repeated filtration through an ultrafilter unit under vacuum.

After test, the above oil sample was subjected to analysis for metallic sludge. The following table reports this value together with corresponding metallic sludge analysis value found in the case of the untreated reference oil only, and a value for the product previous to the removal of its normal graphite content.

	Metallic Sludge % by Weight
Plain oil (without additions)	.270
With Product I	.160
With Product I (Graphite removed)	.210

Assuming that 0.270% of metallic sludge is proportional to the wear produced when unmodified oil only is used as a

lubricant, it is apparent that the presence of the normal colloidal graphite content in this product is responsible for 45.5% of the total wear reduction which the product effected in these tests.   This value is arrived at as follows:

$$\text{Wear Reduction for Product I} = \frac{(.27 - .16)100}{.27} = 40.7\%$$

$$\text{Wear Reduction with Graphite Removed} = \frac{(.27-.21)100}{.27} = 22.2$$

Reduction in Wear due to Graphite   18.5%

% of Total Wear Reduction due to Graphite =

$$\frac{18.5 \times 100}{40.7} = 45.5\%$$

This product has been further studied in connection with oils of various viscosities and origins as follows.

Table J

Numbers in parentheses refer to tests of a series.   The first number in all cases being the control or reference test without additions.   Complete tabular data on these tests will be found in Section IX.

Source of Oil	Bearings Used	Viscosity of Lubricant		
		10-W	S.A.E.-20	S.A.E.-50
Pennsylvania	Ag/Cd		(LII, LII-A, LIII, LIV)	
	Cu/Pb	(LVII, LVIII)	(LV, LVI)	

Source of Oil	Bearings Used	Viscosity of Lubricant		
		10-W	S.A.E.-20	S.A.E.-50
Pennsylvania	Babbitt		(LIX, LX)	
	Steel (Type 3B) Film Strength Tests	(LXVII, LXVIII, LXXI, LXXII)	(LXI, LXII) (LXIII, LXIV LXIX, LXX) (LXXIII, LXIV)	(LXXVII - LXXVIII)
Mid Continent	Steel (Type 3B) Film Strength Tests		(LXV, LXVI)	
California	Steel (Type 3B) Film Strength Tests		(LXXV - LXXVI)	

An inspection of the data outlined in Table K indicates that wear, temperature rise, torque, and seizure pressure, are uniformly improved by the addition of this product.

SECTION VII

THE COMBINED EFFECT OF CORROSIVE AND NON CORROSIVE FILM STRENGTH IMPROVING AGENTS

For the purpose of determining the effect of adding non corrosive film strength improving agents to corrosive film strength improving agents, a series of tests was conducted in which the test sample contained 3% each of tricresyl phosphate and the compound listed in column 1 of Table K which follows.

Table K

Acid or Ester	Seizure Value		Detailed Test Data in Table	% of Corrosion Inhibited
	Without Phosphate	With Phosphate		
1) "Alketone" C-32	1250	1650	XXXIX	68%
2) Oleic Acid	1250	1500	XXXII	80%
3) "Alketoacid" C-18	1500	1500	XXXV	100%
4) Palmitic Acid	1250	1425	XXXVI	86%
5) Ricinoleic Acid	1175	1250	XXXVII	94%
6) "Alketone" C-20	1000	1250	XXXVIII	80%
7) Reference oil only	750	----	I	

The significance of the above tabular data is better understood by reference to the attached graphic presentation, Curve IV. The base line D has been drawn to correspond with the seizure pressure of the reference hydrocarbon oil when tested without additions. Another line has been drawn at 2000 lbs. to correspond with the seizure pressure when tricresyl

phosphate, 3% only, was added to the oil. Curve C was drawn
connecting the seizure pressures for the acids and esters when
added to oil but without the addition of tricresyl phosphate.
Curve B connects the pressure values found when tricresyl phos-
phate was present in the lubricant along with the acid or ester
indicated by the number at the bottom of the curve. These num-
bers correspond with the inhibitor values assigned in Curve II.

In view of the data summarized in a previous table, which
indicated that increases in the concentration of oleic acid only
in the test sample had no added effect on film strength, a
similar series of samples was prepared and tested, containing
fine concentrations of oleic acid and a constant quantity of
tricresyl phosphate as shown in Table L. These results further
tend to confirm the previously expressed view, and I believe
quite generally accepted view, that carboxylic acid additions
in quantity greater than is required to form an oriented layer
over the surfaces offer no advantage.

If we interpret the distance X on Curve IV as a measure
of the corrosive effect of tricresyl phosphate, and Z as prop-
ortional to the ineffectiveness of the inhibitor added, we may
develop the following relations which makes possible the calcul-
ation of the per cent. efficiency of the various inhibitors
tested.

Corrosion without inhibitor = X = A - D

Corrosion with inhibitor = Z = (A - D) - (B - C)

$$= A - B + C - D$$

Per cent. of Corrosion inhibited = $\dfrac{100\ (A-B+C-D)}{A-D}$

The values for the per cent. of corrosion inhibited
column of Table K were calculated by the above formula.

Table L		Oleic Acid		
1%	2%	3%	4%	6%

	1%	2%	3%	4%	6%
Tricresyl Phosphate	3%	3%	3%	3%	3%
Reference Oil	96	95	94	93	91

Seizure Pressure   1%   2%   3%   4%
1500 lbs.- 1500 lbs. - 1500 lbs. - 1500 lbs.

6% = Seizure pressure = 1575 lbs.

The limited amount of data reported here would indicate
that any non corrosive film strength improving agent will, when
added to a corrosive film strength improver, bring about cer-
tain changes in the performance of the combined sample which
are complex functions, and which in any case are not additive
as far as film strength or corrosion is concerned. It is to be
observed that an addition agent which inhibits the corrosion of
tricresyl phosphate completely also entirely overcomes its film
strength improving properties; thus producing a net effect which
is equivalent to the use of the inhibiting agent alone.

With oil samples containing phenyl chloride, the addition

of oleic acid increased the extent of corrosion as indicated by the following data:

Table M

I. Oleic Acid	3.0%	0	3.0%
Phenyl Chloride	3.0%	3.0%	0
Reference Oil	94.0%	97.0%	97.0%
Seizure Torque	1750 lbs.	1500 lbs.	1250 lbs.

It is thought that the double bond in the oleic acid is involved in these results. The addition of one or more chlorine groups would be expected to produce such results as were observed.

Time did not permit the testing of more strongly Polar saturated carboxylic acids in connection with phenyl chloride.

The results with respect to tricresyl phosphate, and perhaps with respect to other corrosive agents which will not add to or form degradation products with carboxylic acids, may be summarized as follows.

Table N

Classification of inhibitors when used in connection with corrosive products which will not form addition or substitution products with the inhibitor, and which have heats of wetting less than the inhibitor.

Molecule	Inhibitor Number or Classification
1) Alpha, beta and Gamma -C = O and -OH substituted Carboxylic acids	10.0 - 9.5

Molecule	Inhibitor Number or Classification
2) Hydroxyl Substituted Carboxylic acids (substitution beyond gamma position)	9.5 - 9.0
3) Saturated Carboxylic Acids	9.0 - 8.5
4) Unsaturated Carboxylic Acids and Hydroxy Ketones of low molecular weight.	8.5 - 7.5
5) Alcohol Ketones of High Molecular Weight	7.5 - 6.0

The method of tentatively assigning the inhibitor numbers will become apparent after inspecting Curve II.

CURVE IV

Class of Inhibitor

SECTION VIII

CONCLUSIONS AND RECOMMENDATIONS FOR
ADDITIONAL STUDY

The findings of the investigation reported here may be
summarized under the heads which follow:

a) Unsaturated carboxylic acids do not corrode bearing
   metals but may accelerate the corrosive action of
   impurities which are present in lubricating oils.
   Acceleration in this case being closely related to
   the ease of formation of addition products by addi-
   tion at the double bond.

b) The presence of chlorinated residues in petroleum
   oils would render the use of unsaturated carboxylic
   acids to lubricating oils hazardous to bearings.

c) Extreme pressure lubricants whose extreme pressure
   properties depend upon the action of chlorinated
   molecules can not be inhibited from attacking metal
   surfaces without loss of their extreme pressure prop-
   erties.

d) It is proposed that the effectiveness of corrosion
   inhibitors can probably be classified according to
   the Polar groups present and the types of and loca-
   tions of double bonds in their molecules, if due con-
   sideration is given to the structure, stability, and
   properties of the corrosive agent whose action is to

inhibited.

e) The reduction in friction losses attendant with the
addition of orienting molecules to lubricating oils
is thought to be the result of the attendant reduc-
tion in linkage of the electromagnetic fields of the
frictional surfaces, as discussed in Section III.

f) The unit pressure at which rubbing surfaces will
seize depends upon the bonding energy of the orienting
molecules to the metal surfaces. It is thought that
this value is closely related to the heat of wetting.

g) The ideal lubricant should contain orienting bodies
of high bonding power with respect to all metals
which it is expected to lubricate. The principle of
selective adsorption should, therefore, be considered
in formulating a lubricant which is to operate in
zones bounded by dissimilar surfaces.

RECOMMENDATIONS FOR FURTHER STUDY

a) The effectiveness of saturated carboxylic acids and
alpha, beta, and gamma carboxyl and hydroxyl substituted
carboxylic acids as corrosion inhibitors should be inves-
tigated. These should be investigated in connection with
aromatic halogenated compounds, sulphur derivatives, in-
cluding sulphur chloride and nitrogen bases.

b) The general application of the corrosion inhibiting
   equation developed in Section VII should be thoroughly
   investigated. It should be studied with gas saturated
   media and through a range of temperatures adequate to
   prove or disprove or limit the practicability of the
   method. If the method should prove to be generally
   applicable it would offer a rapid concise method for
   gaining data with respect to corrosion, which by other
   methods requires months and years to gain imperfect data.

c) An adsorption dynomometer should be developed with a
   pressure applying mechanism actuated by weights and
   levers to eliminate errors and corrections of uncertain
   magnitude encountered with the spring unit used in the
   work reported here. Such a unit should be available at
   reasonable cost. It should preferably be equipped with
   an electrical arrangement for determining losses in order
   to eliminate mechanical difficulties.

d) The possibility of developing a procedure and equations
   for measuring the heat of wetting of metals with fluids
   by adsorption dynomometer methods should be thoroughly
   investigated. This is an important constant in lubrica-
   tion and in other industrial activities and no means is
   at present at hand for its rapid and accurate measurement.
   The correlation between dynomometer seizure values and
   heat of wetting was pointed out in Section V of this rep-
   ort.

E) The comparative 'adsorption' values for colloidal graphite carboxylic acids and alpha, beta, and gamma substituted carboxylic acids should be thoroughly investigated.

SECTION IX - PART B

TABULAR DATA FROM TESTS CONDUCTED ON CERTAIN
MOTOR OIL ADDITION PRODUCTS AS
SOLD IN AMERICAN AND
FOREIGN MARKETS

TESTS CONDUCTED ON CERTAIN MOTOR OIL ADDITION PRODUCTS AS SOLD IN AMERICAN AND FOREIGN MARKETS

REFERENCE OIL   - Selective Solvent Refined Motor Oil
                 (Purchased in sealed container)
VISCOSITY   - 140 sec., at 130°F. (Saybolt Universal)
BEARINGS USED   - Inset construction, full faced Cadmium
                 Silver bearing alloy.
PRESSURE   - Held constant at 50 pounds gross.

In all cases the products subjected to test were added to the reference oil in the proportions recommended by the manufacturers.

SECTION IX - PART C

TESTS CONDUCTED WITH PRODUCT I IN CONNECTION
WITH OILS OF VISCOSITY RANGING FROM 10-W
TO S.A.E. 50 AS CONDUCTED ON FOUR TYPES
OF BEARING SURFACES. THE OILS SELECTED
FOR THESE TESTS INCLUDE REPRESENTATIVE
SAMPLES OF PENNSYLVANIA (PARAFFINIC),
MID CONTINENT (MIXED), AND CALIF-
FORNIA (NAPHTHENIC) ORIGIN.

TESTS WITH PRODUCT I ADDED TO MOTOR OILS OF VISCOSITY RANGING FROM 10-W (90-120 Sec/130° F. S. U.) to S.A.E.-50 (75-105 Sec/210°F. S. U.)

Oils of various origin were selected for these tests to gain information relative to the comparative performance of this particular product. The origin of oils used is as follows:

  Pennsylvania (Paraffinic) -- LII to LXIV, LXVII to LXXIV
  Mid-Continent (Mixed) ------ LXV, LXVI, LXXVII, LXVIII
  California (Naphthenic) ---- LXXV, LXXVI

LXVI.   ADDITION I   VISCOSITY S.A.E.-20   BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	3	90
10	500	8	105
15	750	12 plus	119
20	1000	16.5	140
25	1250	20	180
29-1/2	1500	25	230

LXVII.   ADDITION I   VISCOSITY S.A.E.-10   BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	3.5	90
10	500	8.0	106
15	750	12.5	122.5
17.5	1000	18.5	136

LXVIII.   ADDITIONS I   VISCOSITY S.A.E.-10   BEARINGS-LappedSteel

Time	Load Pounds	Torque	Temperature
5	250	4.5	93
10	500	8.0	106
15	750	13	119
20	1000	17.5	136
25	1250	22.0	158.5
30	1500	28	185
33.5	1750	32.5	207.5

LXIX.   ADDITIONS I   VISCOSITY S.A.E.-20   BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	4.0	100
10	500	8	114
15	750	12.5	136.5
20	1000	16	160
25	1250	20	165
25 plus	1500	26	170

LXX.   ADDITIONS I   VISCOSITY SAE-20   BEARINGS - Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	4	103
10	500	8	150
15	750	13	160

LXX. Continued:-

Time	Load Pounds	Torque	Temperature
20	1000	17	210
25	1250	23	240
30	1500	29	260
30 plus	1750	34	320

LXXI. ADDITIONS I VISCOSITY S.A.E.-10 BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	4.5	92
10	500	8.5	107
15	750	13.5	150
20	1000	18.0	165
20 plus	1250	21	175

LXXII. ADDITIONS I VISCOSITY S.A.E.-10 BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	4	110
10	500	8	106
15	750	13	120
20	1000	19	140
25	1250	23	165

LXXII. continued:-

Time	Load Pounds	Torque	Temperature
30	1500	29	190
35	1750	35	215
36	2000	40	242

LXXIII. ADDITIONS I VISCOSITY S.A.E.-20 BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	4	87.5
10	500	7	102
15	750	11	120
16.5	1000	14	132

LXXIV. ADDITIONS I VISCOSITY S.A.E.-20 BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	3	95
10	500	8	130
15	750	11.5	151
20	1000	16	180
24	1250	19	215

LXXV. ADDITIONS I   VISCOSITY S.A.E.-20   BEARINGS-Lapped Steel

Time	Load Pounds	Torque	Temperature
5	250	4.5	86
10	500	8	142
15	750	13	190
20	1000	18	226
25	1250	22 plus	265
25 plus	1500	26	267

LXXVI. ADDITION I   VISCOSITY S.A.E.-20   BEARINGS-Lapped Steel

Time	Load pounds	Torque	Temperature
5	250	4	105
10	500	8	120
15	750	14	170
20	1000	18	175
25	1250	23	190
30	1500	28	221
35	1750	36	286
35 plus	2000	37	290

LXXVII.   ADDITIONS I   **VISCOSITY** S.A.E.-50   BEARINGS-Lapped
Steel

Time	Load Pounds	Torque	Temperature
5	250	3.5	100
10	500	7	125
15	750	11.5	152
20	1000	15	190
20-1/2	1250	20.5	195

LXXVIII. ADDITIONS I   VISCOSITY S.A.E.-50   BEARINGS-Lapped
Steel

Time	Load Pounds	Torque	Temperature
5	250	2.0	**97.5**
10	500	6.0	116
15	750	10	141
20	1000	13.5	162
25	1250	18	190
29	1500	25	215
