We present an analytical study of magnetic damping. In particular, we investigate the dynamics of a cylindrical neodymium magnet as it moves through a conducting tube. Owing to the very high degree of uniformity of the magnetization for neodymium magnets, we are able to provide completely analytical results for the electromotive force generated in the pipe and the consequent retarding force. Our analytical expressions are shown to have excellent agreement with experimental observations. © 2014 American Association of Physics Teachers.

I. INTRODUCTION

Magnetic braking plays an increasingly significant role in industry. At present, it is commonly used in applications such as electric vehicles, rowing machines, roller coasters and free-fall tower rides in amusement parks, Maglev trains, etc. Other emerging applications include high-speed trains and military vehicles and systems. Magnetic braking has not yet achieved its full potential use in industrial and transportation applications, even though the first patent for a magnetic brake was issued in 1892. There are a number of promising applications in the mining, railroad, and elevator industries, where currently used mechanical brake systems are prone to overheating, mechanical degradation, significant maintenance costs, and periodic failures. Besides being wear free, magnetic brakes are also quiet and odorless. Because they are not dependent on the coefficient of friction, relatively large braking forces can be achieved independent of weather conditions. Furthermore, because their retarding force is proportional to the velocity, they possess an almost ideal mechanism for high-speed safety braking. An improved understanding of magnetic damping is important to the development of future magnetic braking technology. In industry, complex computational models are often used to simulate realistic scenarios of magnetic braking. Here, we have developed a fully theoretical model for a cylindrically symmetric system, which can be used to benchmark these computational models.

We present an analysis of a common demonstration that comprises a cylindrical magnet and a non-ferromagnetic conducting tube in relative motion to each other.1–21 Owing to the interaction between the moving magnet and the induced current in the pipe, the magnet falls quite slowly through the tube, and generates a sense of amazement in students and teachers alike. In this paper, we specifically study the motion of a cylindrical neodymium magnet through a copper pipe of circular cross-section. The azimuthal symmetry of the problem keeps the mathematics tractable and allows us to generate an analytical expression for the electromagnetic force (emf) generated in an arbitrary segment of the tube, as well as the resulting retarding force.

This paper is organized as follows. In Sec. II, we describe the experimental setup used for the demonstration. In Sec. III, we develop a model based on the near-uniformity of magnetization of neodymium magnets and show that the resulting prediction of the magnetic field strength has excellent agreement with the measured values of the field on the axis of the magnet. We also compare the experimental results with the common point-dipole approximation and with a two-monopole approximation. In Sec. IV, we use our model to compute the flux through circular loops of the conducting pipe and generate an expression for the current in a section of pipe of arbitrary length. Then, assuming the length of the tube to be much larger than that of the magnet, in Sec. V we compute the current generated in the pipe. In Sec. VI, we compute the force on the magnet due to the interaction between the magnet and the pipe and compare it with experimental results.

II. EXPERIMENTAL SETUP

The experimental setup is shown in Fig. 1: we use two hanging masses (m and M) to pull a cylindrical neodymium magnet through a copper pipe with varying terminal velocities. Pulling on the magnet from both sides helps to keep it vertical and prevents it from trying to align with the geomagnetic field. We use “smart pulleys” from PASCO to record the position, velocity, and acceleration of the magnet as it falls tower rides in amusement parks, Maglev trains, etc. Other applications include high-speed trains and military vehicles and systems. Magnetic braking has not yet achieved its full potential use in industrial and transportation applications, even though the first patent for a magnetic brake was issued in 1892. There are a number of promising applications in the mining, railroad, and elevator industries, where currently used mechanical brake systems are prone to overheating, mechanical degradation, significant maintenance costs, and periodic failures. Besides being wear free, magnetic brakes are also quiet and odorless. Because they are not dependent on the coefficient of friction, relatively large braking forces can be achieved independent of weather conditions. Furthermore, because their retarding force is proportional to the velocity, they possess an almost ideal mechanism for high-speed safety braking. An improved understanding of magnetic damping is important to the development of future magnetic braking technology. In industry, complex computational models are often used to simulate realistic scenarios of magnetic braking. Here, we have developed a fully theoretical model for a cylindrically symmetric system, which can be used to benchmark these computational models.

We present an analysis of a common demonstration that comprises a cylindrical magnet and a non-ferromagnetic conducting tube in relative motion to each other. Owing to the interaction between the moving magnet and the induced current in the pipe, the magnet falls quite slowly through the tube, and generates a sense of amazement in students and teachers alike. In this paper, we specifically study the motion of a cylindrical neodymium magnet through a copper pipe of circular cross-section. The azimuthal symmetry of the problem keeps the mathematics tractable and allows us to generate an analytical expression for the electromagnetic force (emf) generated in an arbitrary segment of the tube, as well as the resulting retarding force.

This paper is organized as follows. In Sec. II, we describe the experimental setup used for the demonstration. In Sec. III, we develop a model based on the near-uniformity of magnetization of neodymium magnets and show that the resulting prediction of the magnetic field strength has excellent agreement with the measured values of the field on the axis of the magnet. We also compare the experimental results with the common point-dipole approximation and with a two-monopole approximation. In Sec. IV, we use our model to compute the flux through circular loops of the conducting pipe and generate an expression for the current in a section of pipe of arbitrary length. Then, assuming the length of the tube to be much larger than that of the magnet, in Sec. V we compute the current generated in the pipe. In Sec. VI, we compute the force on the magnet due to the interaction between the magnet and the pipe and compare it with experimental results.

Fig. 1. Schematic of the experimental setup. A two-mass pulley system is used to pull a neodymium magnet through a copper pipe.
travels into, through, and out of the pipe. Figure 2 shows that the velocity of the magnet remains constant (at the terminal velocity) for a significant segment of the trajectory.

We find that the dependence of the retarding force on the terminal velocity can be accurately modeled by a linear relation. As we will show in Sec. VI, this linear relationship is replicated by our theoretical analysis. Although researchers have studied the damped oscillatory motion of a magnet in a conducting tube,21 in this work, we limit ourselves to a study of the retarding force for a magnet moving with different terminal velocities.

III. MAGNETIC FIELD DUE TO A NEODYMIUM MAGNET

In order to quantitatively express the magnetic field, we need to develop an appropriate model of the magnet. Several authors have considered the magnet to be a point-dipole,5,15–17,21 which works well for small magnets moving through large-diameter pipes (so long as the magnet is not too close to the inner surface of the pipe). Some authors have also considered a physical dipole constructed of two point monopoles separated by an appropriate distance,4 this too would be a good approximation when the diameter of the magnet is much smaller than the diameter of the pipe. Our aim here is to keep the analysis as general as possible. In particular, we specifically include the case where the diameters of the magnet and the inner surface are comparable so that a strong braking force is generated. In such a case, the point-dipole model does not accurately fit the experimental data.

Neodymium magnets have a very uniform magnetization. This uniformity allows us to approximate the \( \vec{B} \)-field of the cylindrical magnet as if it were produced by two circular disks with uniform magnetic surface charge densities \( \pm \sigma_m \), where \( \sigma_m \) is equal to the magnetization \( M_0 \) of the magnet. The method of determining the \( \vec{H} \)-field is then analogous to the case of finding the electric field of a circular, parallel-plate capacitor with uniform surface charge densities \( \pm \sigma_e \). In Ref. 4, although the authors recognized the applicability of the two-disk model for this situation, they later chose to approximate it using a two-monopole system.

A. Magnetism in a polarizable medium

The magnetic field due to a current density \( \vec{J} \) must satisfy Ampère’s Law

\[
\nabla \times \vec{B} = \mu_0 \vec{J},
\]

where \( \vec{J} = \vec{J}_f + \vec{J}_b \) includes both free and bound current, and the bound current is given by \( \vec{J}_b = \nabla \times \vec{M} \), with \( \vec{M} \) the magnetization (magnetic moment per unit volume). Thus, in the presence of magnetization, we have

\[
\nabla \times \vec{B} = \mu_0 \left( \vec{J}_f + \nabla \times \vec{M} \right).
\]

But for a permanent magnet \( \vec{J}_f = 0 \), so Eq. (2) gives

\[
\nabla \times (\vec{B} - \mu_0 \vec{M}) = \nabla \times \mu_0 \vec{H} = 0,
\]

where the conservative field \( \vec{H} \) is defined such that \( \vec{B} = \mu_0 (\vec{M} + \vec{H}) \). Further, because \( \nabla \cdot \vec{B} = 0 \) we have

\[
\nabla \cdot \vec{H} = -\nabla \cdot \vec{M}.
\]

Comparing this equation with Gauss’ law \( \nabla \cdot \vec{E} = \rho_e / \varepsilon_0 \), we see that the \( \vec{H} \)-field is generated by the “magnetic charge density” \( \rho_m = -\nabla \cdot \vec{M} \) in exactly the same way that the electrostatic field \( \vec{E} \) is generated by the electrical charge density \( \rho_e \). This means we can calculate \( \vec{H} \) exactly as we would calculate \( \vec{E} \) for an electrostatics problem.

B. Magnetic scalar potential for a uniformly magnetized cylinder

Because \( \vec{H} \) is a conservative field, we can write

\[
\vec{H} = -\nabla \Psi_m,
\]

where \( \Psi_m \) is the magnetic scalar potential.23 Using Eq. (4), we then see that the magnetic scalar potential obeys Laplace’s equation

\[
\nabla^2 \Psi_m = -\rho_m = -\nabla \cdot \vec{M}.
\]

For a cylindrical magnet of radius \( R_m \) and length \( L \) having uniform magnetization \( M_0 \) \( \hat{\varepsilon} \) (along the axis of the cylinder), the divergence is zero everywhere inside and outside the magnet and receives non-zero contributions only at the two circular end surfaces. Use of the divergence theorem then shows that the \( \vec{H} \)-field generated by the cylindrical magnet is the same as that generated by the surface charge density \( \vec{n} \cdot \vec{M} \), where \( \vec{n} \) is the outward-pointing normal to the cylindrical surface. Physically, this corresponds to two disks of uniform magnetic surface charge densities \( \pm \sigma_m \) separated by a distance \( L \), where \( \sigma_m = M_0 \) (see Fig. 3). This expression for the \( \vec{H} \)-field is valid both inside and outside the magnet. The \( \vec{B} \)-field is then given by \( \mu_0 \vec{H} \) outside the magnet and \( \mu_0 (\vec{H} + \vec{M}) \) inside.

Because of the symmetry of the problem, the scalar potential on the axis of the cylinder is particularly straightforward to calculate. If we begin with a circular disk of radius \( R_m \) and

\[
-\sigma_m \quad R_m \quad \sigma_m
\]

Fig. 3. A cylindrical (neodymium) magnet is modeled as two disks with uniform magnetic charge densities \( \pm \sigma_m \) located at \( z = \pm L/2 \), respectively.
uniform (magnetic) charge density $M_0$ centered at the origin in the $xy$-plane, then the (magnetic) scalar potential on the $z$-axis is given by

$$\Psi_m(z) = \frac{M_0}{2} \left( \sqrt{R_m^2 + z^2} - z \right). \quad (6)$$

To get the scalar potential for the uniformly magnetized cylinder, we use Eq. (6) and the following superposition. If the origin is located at the center of the magnet and the ends of the cylinder are located at $z = \pm L/2$, as shown in Fig. 3, the resulting scalar potential $\Psi_m$ is given by

$$\Psi_m = \frac{M_0}{2} \left\{ \left[ \sqrt{R_m^2 + \left( z - \frac{L}{2} \right)^2} - \left( z - \frac{L}{2} \right) \right] \right. \right. \left. - \left[ \sqrt{R_m^2 + \left( z + \frac{L}{2} \right)^2} - \left( z + \frac{L}{2} \right) \right] \right\} \right.$$

$$= \frac{M_0}{2} \left[ \sqrt{R_m^2 + \left( z - \frac{L}{2} \right)^2} - \sqrt{R_m^2 + \left( z + \frac{L}{2} \right)^2} + L \right]. \quad (7)$$

The magnetic field outside the magnet and along the $z$-axis is then given by

$$B_z = \mu_0 H_z = -\mu_0 \frac{\partial \Psi_m}{\partial z}$$

$$= \frac{\mu_0 M_0}{2} \frac{\partial}{\partial z} \left[ \sqrt{R_m^2 + \left( z + \frac{L}{2} \right)^2} - \sqrt{R_m^2 + \left( z - \frac{L}{2} \right)^2} \right]. \quad (8)$$

To determine $M_0$ we substitute the physical dimensions of the magnet ($L = 5.1 \text{ cm}$ and $R_m = 1.27 \text{ cm}$) into Eq. (8) and compare it with the experimental data for the axial magnetic field (see Fig. 4). Using the curvefit program in Mathematica we find $M_0 = 1.0335 \times 10^6 \text{ A/m}$, which gives a magnetic dipole moment of $\pi R_m^2 L M_0 = 27 \text{ A m}^2$. Also shown in this figure are the predictions of the point-dipole and two-monopole models. As is evident from Fig. 4, the experimental data are in excellent agreement with the predictions of the two-disk model, which verifies our assumption of uniform magnetization. (It is interesting to note that the two-monopole graph, with magnetic moment $m = 27 \text{ A m}^2$ and length $\ell_m = 3.245 \text{ cm}$ fits the experimental data surprisingly well.)

C. Magnetic field of a cylindrical magnet

To compute the off-axis magnetic field, we begin with the axial potential given in Eq. (6). Except for points on one of the circular end surfaces of the magnet, the magnetic scalar potential $\Psi_m$ satisfies $\nabla^2 \Psi_m = 0$. Hence, the general solution for $\Psi_m$ due to a single disk is given, in spherical coordinates, by

$$\Psi_m(r, \theta, \phi) = \sum_{\ell=0}^{\infty} \left( \frac{b_{\ell}}{r^{\ell+1}} \right) \mathcal{P}_\ell(\cos \theta), \quad (9)$$

where $\mathcal{P}_\ell(\cos \theta)$ are Legendre Polynomials in $\cos \theta$.

As we will see, for the calculation of flux we only need to work in the region $r > R_m$. Hence, $a_\ell = 0$ for all $\ell$ and the scalar potential reduces to

$$\Psi_m(r, \theta) = \sum_{\ell=0}^{\infty} \frac{b_\ell}{r^{\ell+1}} \mathcal{P}_\ell(\cos \theta). \quad (10)$$

In order to determine the $b_\ell$'s, we note that the expression for $\Psi_m(r, \theta)$ in Eq. (10) must be equal to $\Psi_m(z)$ in Eq. (6) when $\theta = 0$ (and hence $r = z$). Therefore,

$$\sum_{\ell=0}^{\infty} \left( \frac{b_\ell}{r^{\ell+1}} \right) = \frac{M_0}{2} \left[ \sqrt{R_m^2 + r^2 - r} \right]. \quad (11)$$

where we have used the fact that $\mathcal{P}_1(1) = 1$ for all $\ell$. By comparing the powers of $r$ on both sides of Eq. (11), we find that the odd coefficients $b_{2\ell+1}$ are zero, and the even coefficients $b_{2\ell}$ are given by

$$b_{2\ell} = \frac{M_0 R_m^{2\ell+2}}{2(\ell+1)!} \prod_{k=0}^{\ell} \left( \frac{1}{2} - k \right). \quad (12)$$

Thus, the magnetic scalar potential $\Psi_m(r, \theta)$, generated by one disk, is given by

$$\Psi_m(r, \theta) = \sum_{\ell=0}^{\infty} \left[ \frac{M_0 R_m^{2\ell+2}}{2(\ell+1)!} \prod_{k=0}^{\ell} \left( \frac{1}{2} - k \right) \right] \frac{1}{r^{2\ell+1}} \mathcal{P}_{2\ell}(\cos \theta)$$

$$= \frac{M_0 R_m}{2} \sum_{\ell=0}^{\infty} \prod_{k=0}^{\ell} \left( \frac{1}{2} - k \right) \left( \frac{R_m}{r} \right)^{2\ell+1} \mathcal{P}_{2\ell}(\cos \theta). \quad (13)$$

Similar to the axial situation [see Eqs. (7) and (8)], to determine the magnetic field of the cylindrical magnet at an arbitrary point $(r, \theta)$, we will again need to add the scalar potentials generated by two such disks with charge densities $\pm M_0$ located at positions $z = \pm L/2$. Hereafter, $\Psi_m(r, \theta)$ will
This article is copyrighted as indicated in the article. Reuse of AAPT content is subject to the terms at: http://scitation.aip.org/termsconditions. Downloaded to IP: 147.125.10.123 On: Thu, 12 Jun 2014 15:58:08

More importantly, because $R_p$ field (outside a distance number of terms in Eq.(13), students can compute the scalar potential method is much more accessible to undergraduate
students. As the magnet travels through the copper pipe, the chang-
ing magnetic flux causes eddy currents to form in the pipe. We will assume that the pipe thickness is small compared to the radius of the pipe (Refs. 14, 15, and 17 have studied the effect of thickness more carefully). We also assume that the magnet falls coaxially through the conducting pipe, and thus an azimuthal symmetry is maintained throughout the motion. In this case, the eddy currents generated in the pipe would form perfect circles perpendicular to the axis of symmetry. Using the magnetic fields given in Eqs. (14) or (15), we will now determine the flux through a circular cross-section of the pipe. We first compute the flux generated by a single disk and then compute the total flux from the magnet by combining the flux from two disks.

To compute the flux through a circular loop of (average) radius $R_p$, a distance $z$ from the disk, we choose a spherical surface, whose center lies at the center of one of the disks of the magnet (see Fig. 5). This particular choice simplifies our calculations considerably. The normal component of the $\vec{B}$-field on this surface is simply the radial derivative of $\mu_0 \Psi_m$. More importantly, because $R_p > R_m$, independent of the value of $z$, the distance of every point of this spherical surface is larger than the radius of the (magnetically) charged disk. This is the reason we were able to set all the $a_i$’s equal to zero in Eq. (9).

Integrating over the spherical surface shown in Fig. 5, the flux $\Phi_m(z)$ through a circular loop a distance $z$ from the front disk is given by

$$
\Phi_m(z) = \left[ \vec{B} \cdot \hat{r} \, da = - \mu_0 \int_S \frac{\partial \Psi_m(r, \theta)}{\partial r} \, da
\right]
$$

while for any point inside the magnet ($|z| < L/2$), we have

$$
\vec{B} = -\mu_0 \left( \nabla \Psi_m - \vec{M} \right).
$$

Thus, we have found an exact expression for the magnetic field (outside a distance $R_m$). The sum can be computed to any desired level of accuracy by including a sufficiently large number of terms. Partovi et al. 14 have carried out a comprehensive analysis for a uniformly magnetized cylinder falling in a pipe by considering the vector potential due to the magnet (see Fig. 5). This particular choice simplifies our calculations considerably. The normal component of the magnetic field is given by the identity $\Phi_m(u) = \left[ \Phi_m^{2\ell+1}(u) - \Phi_m^{2\ell-1}(u) \right]/(4\ell + 1)$, giving a flux

$$
\Phi_m(z) = \pi \mu_0 M_0 R_m^2 \left[ 1 - \frac{z}{R_p^2 + z^2} \right]
$$

where we have substituted the value of $b_0$ in the first term. The above expression for $\Phi_m(z)$ gives the flux due to a single disk. To compute the flux due to the entire magnet, we need to consider two disks with magnetic charge densities $\pm M_0$ separated by a distance $L$. The net flux is then the sum of the contributions from these two disks. In Fig. 6, we plot the magnetic flux through a circular cross-section of the pipe a distance $z$ from the center of the magnet, as well as the flux contributions from $\mu_0 H$ and $\mu_0 M$. Note that a superposition of the $\mu_0 H$ and $\mu_0 M$ contributions gives the magnetic flux, as expected.

### IV. COMPUTATION OF FLUX

As the magnet travels through the copper pipe, the changing magnetic flux causes eddy currents to form in the pipe. We will assume that the pipe thickness is small compared to the radius of the pipe (Refs. 14, 15, and 17 have studied the effect of thickness more carefully). We also assume that the magnet falls coaxially through the conducting pipe, and thus an azimuthal symmetry is maintained throughout the motion. In this case, the eddy currents generated in the pipe would form perfect circles perpendicular to the axis of symmetry. Using the magnetic fields given in Eqs. (14) or (15), we will now determine the flux through a circular cross-section of the pipe. We first compute the flux generated by a single disk and then compute the total flux from the magnet by combining the flux from two disks.

To compute the flux through a circular loop of (average) radius $R_p$, a distance $z$ from the disk, we choose a spherical surface, whose center lies at the center of one of the disks of the magnet (see Fig. 5). This particular choice simplifies our calculations considerably. The normal component of the $\vec{B}$-field on this surface is simply the radial derivative of $\mu_0 \Psi_m$. More importantly, because $R_p > R_m$, independent of the value of $z$, the distance of every point of this spherical surface is larger than the radius of the (magnetically) charged disk. This is the reason we were able to set all the $a_i$’s equal to zero in Eq. (9).

Integrating over the spherical surface shown in Fig. 5, the flux $\Phi_m(z)$ through a circular loop a distance $z$ from the front disk is given by

$$
\Phi_m(z) = \left[ \vec{B} \cdot \hat{r} \, da = \mu_0 \int_S \frac{\partial \Psi_m(r, \theta)}{\partial r} \, da
\right]
$$

$$
= \sum_{\ell=0}^{\infty} b_{2\ell+1} \left( \frac{1}{r^{\ell+1}} \right) \int_{r=0}^{r=R_m^2 + z^2} P_{2\ell}(\cos \theta) \sin \theta \, d\theta \, d\phi
$$

$$
= 2\pi \mu_0 \sum_{\ell=1}^{N} \frac{(2\ell + 1) b_{2\ell}}{(R_p^2 + z^2)^{\ell+1}} \int_{\rho=0}^{\rho=R_m} P_{2\ell}(u) \, du,
$$

where in the last line we defined $u = \cos \theta$ and $u_p = z/\sqrt{R_p^2 + z^2}$. We can compute the integral in Eq. (16) using the identity $P_{2\ell}(u) = \left[ P_{2\ell+1}(u) - P_{2\ell-1}(u) \right]/(4\ell + 1)$, giving a flux

$$
\Phi_m(z) = \pi \mu_0 M_0 R_m^2 \left[ 1 - \frac{z}{R_p^2 + z^2} \right]
$$

$$
+ 2\pi \mu_0 \sum_{\ell=1}^{N} \frac{(2\ell + 1) b_{2\ell}}{(R_p^2 + z^2)^{\ell+1}} \left[ \frac{z}{\sqrt{R_p^2 + z^2}} - P_{2\ell+1} \left( \frac{z}{\sqrt{R_p^2 + z^2}} \right) \right],
$$

where $P_{2\ell}$ is the Legendre polynomial of degree $2\ell$. The above expression for $\Phi_m(z)$ gives the flux due to a single disk. To compute the flux due to the entire magnet, we need to consider two disks with magnetic charge densities $\pm M_0$ separated by a distance $L$. The net flux is then the sum of the contributions from these two disks. In Fig. 6, we plot the magnetic flux through a circular cross-section of the pipe a distance $z$ from the center of the magnet, as well as the flux contributions from $\mu_0 H$ and $\mu_0 M$. Note that a superposition of the $\mu_0 H$ and $\mu_0 M$ contributions gives the magnetic flux, as expected.

### V. COMPUTATION OF EMF

In order to compute the emf through a circular cross-section of the conducting pipe a distance $z$ from the center of the magnet, we need to determine the change in flux through the loop during a time interval $\Delta t$. We take the $z$-direction pointing up and assume the magnet falls with a constant velocity $\vec{v} = (dz/dt) \hat{z} = -v_0 \hat{z}$. The emf is then given by

$$
E = \oint \vec{E} \cdot d\vec{l} = -\frac{d\Phi_m}{dt} = -\frac{d\Phi_m}{dz} \frac{dz}{dt} = v_0 \frac{d\Phi_m}{dz}.
$$

The electric field in the wall of the pipe is therefore $E_{\phi}(r) = E/2\pi r$, where $r$ is the distance from the axis of the pipe. Hence, the current density in the pipe is given by $J_{\phi} = \sigma_0 E_{\phi} = \sigma_0 E/2\pi r$, where $\sigma_0$ is the conductivity of the pipe (in this case $\sigma_0 = 4.91 \times 10^7$ S/m for copper). The current $\Delta I$ through a section of the pipe of thickness $dr$ and length $\Delta z$ can then be calculated as
This article is copyrighted as indicated in the article. Reuse of AAPT content is subject to the terms at: http://scitation.aip.org/termsconditions. Downloaded to IP: 147.126.10.123 On: Thu, 12 Jun 2014 15:58:08

Contributions of the various fields to the flux $\Phi_m(z)$ through a cross-section of the pipe a distance $z$ from the center of the magnet. Contributions are from $\mu_0 H$ (top), $\mu_0 M$ (middle), and $B$ (bottom) for our magnet of length $L = 5.1$ cm.

\[
\int dl = \int_{R_1}^{R_2} J_\phi(r) \, dr \Delta z = \frac{\mu_0 \sigma_c}{2\pi} \ln \left( \frac{R_2}{R_1} \right) \frac{d\Phi_m}{dz} \Delta z
\]

\[= \frac{\mu_0 \sigma_c}{2\pi} \ln \left( \frac{2R_p + \delta}{2R_p - \delta} \right) \frac{d\Phi_m}{dz} \Delta z, \tag{19}\]

where $R_1$ and $R_2$ are the inner and outer radii of the pipe, $\delta = R_2 - R_1$, $R_p = (R_1 + R_2)/2$ is the average radius of the pipe. In our case $\delta/2R_p \approx 0.04 \ll 1$, so we can expand the logarithm in powers of $\delta/R_p$ to get

\[
\Delta I = \frac{\mu_0 \sigma_c}{2\pi} \left( \frac{\delta}{R_p} \frac{1}{12 R_p^3} + \cdots \right) \frac{d\Phi_m}{dz} \Delta z
\]

\[\approx \frac{\mu_0 \sigma_c}{2\pi R_p} \frac{d\Phi_m}{dz} \Delta z, \tag{20}\]

to lower order. Therefore, the total current through a section of the pipe from $z_1$ to $z_2$ is given by

\[I = \frac{\mu_0 \sigma_c}{2\pi R_p} \left[ \Phi_m(z_2) - \Phi_m(z_1) \right]. \tag{21}\]

Verifying this expression for current was a difficult task. We removed a small cylindrical slice (a few millimeters in length) from the middle of the pipe and replaced it with a loop of very thin magnetic wire in series with a large resistor. The gap was kept small to ensure that the velocity of the magnet remained constant. By finding the voltage across the resistor (measured in $\mu V$), we indirectly measured the current in the loop and inferred what the current would have been in the absence of the resistor. Figure 7 shows the current generated in a loop as the magnet passes through it, along with our theoretical prediction. Here, we see that there is reasonably good agreement between the positions of the peaks, but less so for the heights. This discrepancy is caused by the uncertainty in measuring very low voltages. Fortunately—as demonstrated in Sec. VI—the retarding force is much easier to measure than the induced current, so we will obtain much better agreement between theory and experiment when investigating the force as a function of velocity.

VI. COMPUTATION OF RETARDING FORCE

Because the magnet travels with a constant velocity $\bar{v}$, conservation of energy stipulates that the (thermal) energy loss in the conducting pipe per unit time will be equal to $|\bar{F} \cdot \bar{v}|$, where $\bar{F}$ is the magnetic retarding force. Thus, if we know the power loss and the magnet velocity we can determine the retarding force. To compute the power loss in the pipe, we first determine the differential loss over an infinitesimal length $\Delta z$ of the pipe. This loss is given by

\[
dP = (dl)^2 (dR) = (J_\phi \, \delta \, \Delta z)^2 \times \text{Resistance of length } dz
\]

\[= \left( \frac{\mu_0 \sigma_c \delta}{2\pi R_p} \frac{d\Phi_m}{dz} \Delta z \right)^2 \times \frac{2\pi R_p}{\sigma_c \delta \Delta z}, \tag{22}\]

Assuming the pipe to be much longer than the magnet, we find that the total power loss is given by

\[\frac{1}{2} m \bar{v}^2 = \frac{1}{2} \frac{\mu_0 \sigma_c \delta}{2\pi R_p} \frac{d\Phi_m}{dz} \Delta z \text{,}
\]

where $m$ is the mass of the magnet and $\bar{v}$ is its velocity.
VII. CONCLUSION

We studied the effect of a cylindrical neodymium magnet moving along the axis of a cylindrical conducting pipe. Using the symmetry of the setup and the near uniformity of the magnetization of a neodymium magnet, we were able to develop an analytical model for the induced surface current density and resulting retarding force. The analytically predicted current distribution and the retarding force show excellent agreement with experimental observation. Because we were able to use the magnetic scalar potential technique, which bears a strong resemblance to electrostatics, our analysis is comparatively more accessible to undergraduates than other approaches. In addition, students can compute the flux to any desired level of accuracy by keeping a sufficiently large number of terms in the expansion of the scalar potential.

ACKNOWLEDGMENT

Two of the authors (B.I. and M.K.) would like to thank Loyola University Chicago for the Mulcahy scholarship, which helped make their undergraduate research possible. A.G. would like to thank the Center for Experiential Learning at Loyola University Chicago for an Engaged Learning Faculty Fellowship that provided partial support for this research. The authors would also like to thank Christopher Kabat for his help in designing the experiments. The authors also acknowledge two anonymous referees, whose detailed comments challenged us to carry out an extensive analysis of sheet resistance to determine the conductivity of the pipe and to conduct a comparative study of various competing models, which provided additional support to our analysis.

A physical dipole consists of two magnetic charges \( (\pm q_m) \) of opposite polarity separated by a distance \( l_m \). The magnetic field due to a monopole is assumed to be \( \frac{\mu_0 q_m}{4 \pi r^2} \). The magnetic charge \( q_m \) and the separation \( l_m \) are determined by stipulating that the dipole moment \( (q_m l_m) \) be equal to that of our magnet \( (\pi R_m^2 M_0) \). Additionally, we demand that the magnetic field on the axis of two monopoles situated at \( z = \pm \frac{1}{2} l_m \) has a best fit with the experimental data. This generates a best estimate for \( l_m \) of 3.245 cm.

26We computed this frictional force by forming an Atwood machine type experiment with varying \( \Delta m \), but keeping \( m_1 + m_2 = 600 \) g.

**Demonstration Induction Coil**

From the 1916 catalogue of the L. E. Knott Apparatus Company: “This type of coil is of value in the study of the office of the primary in induction coil construction. Both primary and secondary are mounted on a polished mahogany box, but the mount is designed so that the secondary may be adjusted to enclose varying amounts of the primary. This instrument is handsomely finished, all brass parts polished and lacquered, and will give a ¼-inch spark…$5.00” This instrument is on long term loan to the Greenslade Collection from the Appalachian State University Physics Department.
